ABSTRACT

Liquid metal-based sensors have great opportunities in various applications such as health monitoring, intelligent artificial skin, and soft robotics. However, current liquid metal-based
pressure sensors suffer from low pressure sensitivity, low signal reliability, and poor interconnection properties. This paper introduces sensitivity engineerable, reliable liquid metal-based pressure sensor for multifunctional wearable applications with a robust interconnection structure. Herein, we investigated the effects of dimensions of rigid microbumps on the liquid metal-based soft pressure sensor. Furthermore, two different types of rigid microbump structures such as embedded bump (E-bump) and anchored bump (A-bump) were designed and integrated with liquid metal microchannel using multi-material 3D printing technology and it enabled the engineering of pressure sensitivity for different purposes. High sensitivity was achieved with E-bump structures and robust interconnection structure was realized with A-bump structures.

Integration of E-bumps has increased the average sensitivity of the sensor to 0.0727 kPa\(^{-1}\) (5.43 times higher) and A-bump integration has decreased the average sensitivity to 0.0004 Pa\(^{-1}\) (91.65 times lower) in the range of 0-50 kPa, as compared to the pressure sensor without any microbumps.

Therefore, the liquid metal interconnection was established with the A-bump structures for reliable pressure monitoring in practical wearable applications. These characteristics allow demonstration of the multifunctional wearable electronic applications, including a fingertip pressure sensor glove.
for wireless multi-position wrist pulse monitoring as traditional East Asian medicine (TEAM) pulse diagnosis and a wireless human-machine interface (HMI) device.

INTRODUCTION

Wearable pressure sensors are under tremendously high demand of improvement due to their diverse applications such as mobile healthcare, entertainment, and virtual/augmented reality (VR/AR) systems. In contrast to conventional sensors, wearable pressure sensors need to satisfy several requirements such as high sensitivity, high flexibility, wearability, signal stability, lightweight, and low cost. Various attempts have been made to fulfill these requirements, specifically to increase the sensitivity of the wearable pressure sensors. To increase the pressure sensitivity, elastomers and wide ranges of functional materials such as graphene\textsuperscript{1-4}, carbon black\textsuperscript{5-7}, nanowires\textsuperscript{8, 9}, and nanoparticles\textsuperscript{10, 11} have been utilized, which can be classified as solid-state pressure sensors. These sensors have suffered from long term instability, limited stretchability, and signal drifting due to the difference in mechanical properties between the flexible substrate and functional sensing materials. Therefore, liquid-state sensors based on liquid metals and ionic liquids have been proposed to overcome the limitations of solid-state sensors for wearable
electronics applications. Especially, the stretchability of liquid state sensors is less limited due to
the utilization of liquid electrodes as the sensing materials. Due to negligible friction at the
interface of liquid and encapsulating elastomer, the characteristics of liquid electrodes are not
degraded by harsh mechanical loadings. Ionic liquids have high degree of freedom in the
engineered material properties by using diverse chemicals such as salts in the liquid or gel-state.
Therefore, the ionic liquid-based pressure sensors can have high pressure sensitivity. However,
they suffer from poor electrochemical stability and require alternating current measurement to
avoid charging effect. Furthermore, they have relatively slow responses due to ion transfer
process\textsuperscript{12-15}. On the other hand, liquid metals are promising materials due to their excellent
electrical and thermophysical properties. As one of the liquid metallic materials, Galinstan has
unique material properties such as, self-healing capability, low melting point around the room
temperature, high electrical conductivity and nontoxicity that give superior promise for use in
wearable soft electronic devices. However, conventional liquid metal-based pressure sensors have
shown low pressure sensitivity and thus there have been some effort to improve their sensitivity.
Previous studies have utilized triple state of liquid metal microchannels\textsuperscript{16}, diaphragm pump
structuring\textsuperscript{17}, and internalization of rigid objects within the liquid metal channels\textsuperscript{18}. In our previous
study, we proposed to develop a liquid metal-based pressure sensor by utilization of multi-material 3D printing method. The pressure sensitivity of the liquid metal-based pressure sensor has increased by integration of 3D printed rigid microbump array onto the liquid metal channel\textsuperscript{19}. However, in our previous study, parametric study about the effect of dimensions of the rigid microbump on the liquid metal-based pressure sensor was not conducted. Furthermore, there have been very few studies about the strategies to suppress the pressure sensitivity in the interconnection area of liquid metal-based sensors for mechanically robust and stable wearable device integration.

In this study, we introduce a 3D-printed rigid microbump array-integrated liquid metal-based soft pressure sensor that features an optimization of the microbump dimensions and the integration of the optimized microbumps (E-bump and A-bump) into a fingertip pressure sensor. The structure of the proposed soft pressure sensor is constructed via multimaterial fused deposition modeling (FDM). The 3D printed structure is divided into two different layers such as water-soluble microchannel mold and rigid microbump arrays that are simultaneously embedded into the elastomer. Liquid metal channels are formed by sacrificing the water-soluble microchannel mold and then by filling the channels with the liquid metal. The rigid microbump arrays stand above the microchannels through the embedded structure between the microchannel and elastomer.
Importantly, the current study demonstrates wide applications of fingertip pressure sensor for wearable electronics based on liquid metal, which makes use of the increased sensitivity in the pressure-sensitive area by E-bump. Moreover, the interconnections of the constructed sensors were not significantly affected by external stimuli, owing to the decreased pressure sensitivity by the A-bump. Herein, we illustrated the applications of the proposed fingertip pressure sensor in traditional East Asian medicine that can monitor the wrist pulsation by palpation. Furthermore, the proposed wearable fingertip pressure sensor was applied to remote controlling and the Flappy Bird game.

RESULTS AND DISCUSSION

Design and Fabrication

The 3D-printed rigid microbump-integrated liquid metal-based soft pressure sensor is basically divided by four main parts: bottom layers, liquid metal channels, 3D-printed microbumps, and top layer. The detailed schematic of the sensor is presented in Figure 1a-c. The top and bottom layers of the sensor are made of Dragon SkinTM 10 with a low elastic modulus ($E = 150$ kPa for $\varepsilon = 100\%$) and an extremely high stretchability (1000%). The excellent mechanical properties of Dragon SkinTM and liquid metal provide a perfect reversibility and robustness in stretching and twisting deformations (Figure 1d). Briefly, the 3D-printed rigid microbump-integrated liquid metal-based soft pressure sensor is fabricated with a multi-nozzle fused deposition modeling (FDM) 3D printing process. The schematic of the fabrication processes can be found in Figure S1. There are two layers for 3D printing, which are polylactic acid (PLA) and polyvinyl alcohol (PVA). PVA is used as a sacrificial layer for the formation of liquid metal based microchannel.
On the other hand, PLA is used for the rigid microbump array formation. To fabricate the microchannels, the PVA layer is removed by water intrusion while the rigid PLA microbumps are monolithically integrated onto the elastomer layer. Then, the microchannel is filled with Galinstan (Figure 1c). The electrical interconnection is made by embedding electrical wires into the liquid metal filled microchannel. Finally, the 3D-printed rigid microbump-integrated liquid metal-based soft pressure sensor is embedded onto a thimble-shaped elastomer (Figure S2).
Figure 2. Working principle of 3D-printed microbump integrated liquid metal soft pressure sensor.

(a) Geometry of microbump integrated liquid metal pressure sensor. $k_t$: thickness ratio of microbump to top elastomer layer ($t_b/z$). $k_w$: width ratio of microbump to liquid metal channel ($w_b/w_0$).

(b,c) Effect of $k_w$ and $k_t$ on $\chi$. When $k_t$ and $k_w$ approach 1, $\chi$ also approaches to 1, which is theoretically a complete transmission of pressure from the surface to microchannel.

(d) FEM simulation of the integration of microbump. (e) $\chi$ vs Arc length when $k_w=1$. When $k_t=0$, there is a
parabolic distribution of $\chi$ with respect to the arc length (black dotted curve). Here, the black solid line represents the average $\chi$ for the parabolically distributed $\chi$ values. However, when the microbump is integrated, there is a constant $\chi$ with increased value across the arc length. (f) $\chi$ vs Arc length when $k_t=0.7$. Only the surface where microbump exist has a constant value and the other part shows a parabolic curve of $\chi$. (g, h) Effect of $k_w$ and $k_t$ on $E_{\text{eff}}$. Black solid curve represents change of $E_{\text{eff}}$ by varying $k_t$ while $k_w$ is fixed at 0.5. Blue dotted curve represents the change of $E_{\text{eff}}$ by varying $k_w$ while $k_t$ is fixed at 1. As $k_t$ and $k_w$ approach 1, $E_{\text{eff}}$ decreases by more than 10%.

**Design of Pressure Sensitivity**

When pressure is applied to the liquid metal microchannel, the cross-sectional area of the microchannel decreases and it leads to the increase of the electrical resistance of the microchannel. Under the application of a normal stress ($\sigma_z$), the change of the height of the microchannel ($\Delta h$) can be described as Eq. (1) and the relative change of the resistance can be written as Eq. (2), which is based on the linear elastic fracture mechanics (LEFM) 20 (Figure S3a-b).

$$\Delta h = \frac{2(1-v^2)w\sigma_z}{E} \quad \text{Eq. (1)}$$
\[
\frac{\Delta R}{R_0} = \left( \frac{1}{1 - \frac{2(1-\nu^2)}{E} \chi \sigma_z (w/h)} - 1 \right)
\]

Eq. (2)

where w and h are the width and height of the microchannel, \( \nu \) is the Poisson’s ratio, E is Young’s modulus of the elastomer and \( \chi \) is the correction factor. When the normal stress (\( \sigma_z \)) is applied on the surface of the elastomer, the magnitude of the stress decreases in Z direction. The pressure applied to the top surface of the microchannel is diminished by the correction factor \( \chi \). According to the equation, to increase the relative resistance change, the change of cross-sectional area of the microchannel should be increased, which is dependent on the transmitted pressure to the microchannel and the effective mechanical modulus of the structure. Accordingly, there are two strategies to increase the pressure sensitivity: (i) increasing the correction factor \( \chi \) or (ii) decreasing the effective mechanical modulus of the structure. In previous studies\(^{20-22} \), researchers tried to change the effective mechanical modulus by changing the geometry of microchannel (w/h).

To investigate the geometric effect of liquid metal pressure sensor, three parameters are defined (i.e. z: thickness of the top layer, h: height of the microchannel, and w: width of the microchannel) and the resistance change over the same applied pressure was calculated using finite element method (FEM) simulation (COMSOL) (Figure S3c). It is found that the pressure sensitivity is
inversely proportional to the height of the microchannel and the thickness of the top layer and proportional to the width of the microchannel.

In our study, we found that the integration of rigid microbump can increase the correction factor and decrease the mechanical modulus of the structure. The schematic view of the integrated microbump and microchannel geometry is shown in Figure 2a. We defined that $k_t$ is the ratio of the thickness of top elastomer ($z$) and thickness of microbump ($t_b$) and $k_w$ is the ratio of the width of liquid metal microchannel ($w_0$) and the width of microbump ($w_b$). When $k_t$ is 1, the rigid microbump is totally covering the top surface of the microchannel, and when $k_t$ is 0, there is no microbump. When $k_w$ is 1, the width of the microbump and that of the microchannel are the same, and $k_w > 1$ means that the width of the microbump is larger than that of the microchannel, and vice versa.
Figure 3. Design of microbump with respect to the value of $k_t$ and $k_w$. (a) Single microchannel sensor test for the evaluation of the effect of microbump (Scale bar = 10mm). (b) Effect of $k_t$. When $k_t$ approaches 1, the sensitivity significantly increases. (c) Effect of $k_w$. When $k_w$ is below 1, there is an increase of the sensitivity by increasing $k_w$. When $k_w$ is larger than 1, A-bump prevents the deformation of microchannel, decreasing the sensitivity. (d) 10,000 cyclic loading with the repeating compressive pressure of 0-15 kPa. (e) Effect of length of microbump on bending. L=1 mm, 4mm, and 1/1mm cases are experimentally observed. Negligible signal change
was observed when L is 1 mm and 1/1 mm (i.e. two 1 mm long microbumps are integrated with a gap of 1 mm).

First, when the microbump exists \((k_t > 0)\), the rigid microbump helps the transmission of the applied stress from the top surface of the elastomer to the that of the microchannel. Since the rigid microbump, having an elastic modulus of 3.5 GPa, does not deform due to its high elastic modulus, it directly transmits the pressure applied on the top of the microbump to the bottom. It means that the correction factor \(\chi\) is changed to \(\chi = \chi(z - t_b) = \chi(z')\) by introducing the microbump. Thus, the integration of the rigid microbump changes the effective thickness of the top elastomer from \(z\) to \(z'\) and increases the magnitude of the stress transmitted to the microchannel. Therefore, the pressure transmitted to the microbump can be established as \(\chi(z') \sigma_z\). (Figure 2b). Theoretical prediction of \(\chi\) is done by Bousinesq's method (Figure S4). When the correction factor \(\chi\) is close to 1, almost complete transmission of the pressure from the top surface of elastomer to the microchannel occurs. \(\chi\) approaches 1 when \(k_t\) is above 0.6 and \(k_w\) is close to 1 (Figure 2c). It infers that, as \(k_w\) increases, the microbump covers more area of the microchannel and delivers more stress to the microchannel with higher correction factors. When the load is applied, the top surface profile of microchannel is deformed as shown in Figure 2d-f. The top surface of microchannel without
microbump has a parabolic curve according to the arc length (x). When a microbump with \( k_w = 1 \) is integrated, the surface profile become straight in the region in contact with the rigid microbump as there is no deformation in the rigid microbump (Figure 2e). When \( k_w \) is below 1, the top surface profile becomes a combination of straight line at the center and parabolic curve at the other areas. The average \( \chi \) appear the descent below 0.5 and the ascent above 0.5 of \( k_w \). Therefore, \( k_t \) should be close to 1 and \( k_w \) should be above 0.5 for the enhancement of pressure sensitivity (Figure 2f).

Second, the integration of microbump can also increase the pressure sensitivity by decreasing the effective mechanical modulus of the composite structure. The liquid metal pressure sensor structure can be assumed as the composite structure composed of two different materials with different mechanical moduli (\( E_1 \): elastomer and \( E_2 \): elastomer + liquid metal). Because the pressure is applied on the top surface and incurs the same deflection of material, effective modulus can be simply assumed as Eq. (3), where \( v_1 \) and \( v_2 \) are the volume fractions of materials 1 and 2, respectively. Furthermore, material 2 is a composite of material A (elastomer) and B (liquid metal) with the same stress, which lead to the effective modulus as below, when \( v_{2A} \): volume fraction of material A, and \( v_{2B} \): volume fraction of material B. (Figure 2g)
\[ E_{eff} = E_1 v_1 + E_2 v_2 \]  \hspace{1cm} \text{Eq. (3)}

\[ E_2 = 1 / \left( \frac{v_{2A}^2}{E_A} + \frac{v_{2B}^2}{E_B} \right) \]  \hspace{1cm} \text{Eq. (4)}

When the microbump is integrated into the microchannel, the volume fraction \( v_{2B} \) increases, leading to the decrease of \( E_2 \). Here, the elastic modulus of rigid microbump is not considered because the interface between the microbump and the elastomer’s inner surface is not chemically bonded, but physically overhang. Although the friction or physical interaction at the interface would make a reduction in the decreasing ratio from the increase of \( v_{2B} \), the effective modulus decreases as \( k_t \) and \( k_w \) increases. (Figure 2h) This result could be supported by the finite element method (FEM) simulation result, showing that the cross-sectional area has further reduced when the rigid microbump is integrated into the microchannel under the same pressure (Figure S5).
Figure 4. Structure and assessment of fingertip pressure sensor (a) Schematic view of fingertip pressure sensor that is based on a 3D-printed rigid microbump integrated liquid metal-based pressure sensor (b) The variation of the relative resistance with pressure and the sensitivity within ranges of 0-10, 10-30, and 30-50 kPa. (c) Relative resistance change of the interconnection area
with/without anchored microbump under pressure. (d) Dynamic response of the sensor to varying pressure application.

The microbump could be classified into two types according to the width of microbump ($k_w$): E-bump and A-bump. For an E-bump, $k_w$ is equal to or less than 1, providing a stable and robust structure for the pressure sensor with a high pressure sensitivity. For an A-bump, $k_w$ is larger than 1, the width of microbump exceeding that of the microchannel, which reduces the pressure sensitivity due to the A-bump on the sidewall of liquid metal microchannel.

Although the correction factor $\chi$ is increased by increasing $k_w$, A-bump prevents the microchannel from mechanical deformation by the mechanical anchoring. To evaluate the performances of each microbump design, single channel liquid metal-based pressure sensors with various microbump geometries were fabricated and characterized (Figure 3a). When $k_t$ increased, the response significantly increased as compared to the conventional liquid metal pressure sensor without any microbump ($k_t=0$). Especially when $k_t = 1$, the sensor showed very high-pressure sensitivity even in the low-pressure range (< 30 kPa). Also, when $k_w$ increases up to 1, the responses were enhanced compared to the liquid metal sensor without microbump. However, when $k_w = 1.5$, A-bump
inhibited the change of microchannel geometry, resulting in a reduced pressure sensitivity. Therefore, when an E-bump, which is a rigid microbump with $k_w < 1$, is integrated into the microchannel, the external pressure leads to a significant reduction of the cross-sectional area of the microchannel by locally concentrated deformation below the microbumps while the correction factor increases and effective modulus decreases. Consequently, the sensor response to the same applied pressure would be greatly improved by employing an E-bump (Figure 3b-c). In addition, under 10,000 cyclic loading with the repeated compressive pressure of 0-15 kPa showed a long-term stability and mechanical durability of the sensor (Figure 3d). In the 8th cycle and 8,960th cycle, the normalized resistance of change of the base lines are 0.00611 and 0.00636, respectively, with an increase of 4.1% only. The sensor showed a stable performance of measuring the pressure after 10,000 repetitive cycles. These results yield that the sensor shows a good long-term stability. The bending test showed that when the length of microbump $L$ is 1 mm (case I), the relative resistance change is negligible. When $L$ is 4mm (case II), the relative resistance increases to 0.027. Therefore, to reduce the effect of bending, multiple short microbumps with small gaps can be integrated instead of a single long microbump. The bending insensitivity is verified by the experimental result in which two 1 mm long microbumps are integrated with a gap of 1 mm (case
III) (Figure 3e). In order to investigate the detection limit of the sensor, small pressures were applied to the sensing area from 0 to 660 Pa (Figure S6). The detection limit was evaluated as $LOD = \frac{3\sigma}{b}$, where $\sigma$ is the standard deviation of the response and $b$ is slope of calibration curve$^{23}$. The detection limit of the sensor was calculated as 15 Pa. The sensitivity, detection range and insensitive interconnection properties of the proposed sensor are comparable with previously introduced liquid metal-based pressure sensors and summarized in Table S1 in the Supporting Information.

Application of the fingertip pressure sensor to pulse measurement in Traditional East Asian Medicine: (a) Image of the measurement method of fingertip pressure sensor and structure design of the data acquisition and wireless communication platform (b) Wrist pulse waveforms of the test subject on the Chi, Guan, Cun locations. (c) Single-region pulse wave measurement on the Guan position with different pressures.
Integration of E-bump and A-bump to wearable and wireless liquid metal-based fingertip pressure sensor

In order to demonstrate a wide range of applicability of the E-bump and A-bump structures, a wireless liquid metal-based fingertip pressure sensor has been developed. The fingertip pressure sensor is composed of two parts; pressure sensing area and interconnections. The pressure sensing area has a serpentine pattern of microchannel, having an area of $10 \times 10 \text{ mm}^2$. We designed $k_v/k_w$ of E-bump as 0.5/1.0 to enhance the pressure sensitivity of the sensor and that of A-bump as 0.5/2.0 to minimize the pressure sensitivity. The dimensions of the E-bump and A-bump were $0.4 \times 1 \times 0.4 \text{ mm}$ and $1.5 \times 3 \times 0.4 \text{ mm}$ (width, length, thickness), respectively. The pressure sensing area had 3×4 E-bump array, and the interconnection area had 1×3 A-bump array (Figure 4a). The geometry of the interconnection was designed to smoothly cover the finger when it is made into the form of a thimble. The length of the interconnection was designed as the end of the interconnection that could meet at the middle phalanx of the finger. The detailed fabrication process is demonstrated in Figure S2. The total length of the fingertip sensor was 40 mm and the thickness was 1 mm. Figure 4b shows the experimental data of the relative resistance change of the fingertip pressures sensor with and without E-bumps. The pressure response test graph is
divided by three different sections such as 0-10 kPa, 10-30 kPa, and 30-50 kPa. The correlation of coefficient (R²) is 0.961, 0.977, 0.997 for each of these ranges, respectively. Meanwhile the sensitivity is 0.013 kPa⁻¹, 0.071 kPa⁻¹, and 0.118 kPa⁻¹ for each of these ranges, respectively. E-bump integrated pressure sensor’s average sensitivity is 0.0727 kPa⁻¹ and it is 5.43 times higher than that of the pressure sensor without E-bumps at 0-50 kPa range. This can be attributed to the pressure sensitivity enhancement by E-bump as explained above. On the other hand, the interconnection area is another essential part of the wearable devices for signal transmission. Previously developed liquid metal-based sensors have not been equipped with special structures to prevent the effect of external stimuli on the interconnection area that cause distortion in the measured signal. In the present study, with the integration of A-bumps into the interconnection area, it is possible to achieve an excellent signal stability in the wearable device and to secure a high reliability in the pressure sensing data. As shown in Figure 4c, A-bump integrated interconnection sensitivity is 0.0004 Pa⁻¹ in the range of 0-50 kPa, which 91.65 times lower than that of the pressure sensor with any microbumps. Figure 4d shows the reversible sensor response to dynamic loading at varying pressures. In the case of Figure 3b, we conducted the experiment with a single microbump structured sensor that can be referred in the Figure 3a. The single
microbump structured sensor length is shorter (20 mm) than the fingertip pressure sensor (138 mm) that can be referred in Figure 4a. Therefore, total resistance was larger for wearable fingertip pressure sensor than for the single microbump structured sensor in Figure 3a. In result, the increased the base resistance ($R_0$) of the sensor reduced the response ($\Delta R / R_0$) of the sensor.

Potential applications of the fingertip pressure sensor

Application 1: Pulse Measurement in Traditional East Asian Medicine (TEAM)

Identification of health status and diagnosis of disease through pulse palpation have been carried out in TEAM for a long time. Pulse palpation is one of four major examinations in TEAM. TEAM doctors use pulse palpation at three locations (Cun, Guan, Chi) on both wrists to check up the health conditions of the patients and specific organ conditions\textsuperscript{23}. The pulse measurement has two classifications. First, pulse is measured at a single position, specifically in Guan. Second, pulse is measured in three positions (Cun, Guan, Chi), which depends on the theory of Three Positions and Nine Indicators (TPNI). TEAM doctors go through an experience-based education program to make the medical assessments by applying different pressures and processing the pulse measurement at the three locations without instruments. Recently, researchers have made various
attempts to prove identification of health condition and diagnosis of disease scientifically through quantitative pulse measurement systems. However, previously developed systems did not allow the TEAM doctors to get involved in the pulse measurement process. In other words, the measurements were made by attachment of sensors directly on the human wrist or on the mechanical measurement devices, thereby the TEAM doctors could not sense the wrist pulse during the measurement period.

However, there is a strong demand from TEAM doctors on the wearable pulse measurement systems that they can wear on their fingers to apply various pressures on the human wrist for acquisition of different pulse palpation patterns according to TPNI theory. Therefore, the present work has proposed a wireless and wearable soft fingertip pressure sensor that highly interacts with TEAM doctors on pulse palpation. It is lightweight, easy to operate, and convenient in pulse measurement to identify health status and to diagnose the diseases. Figure 5a shows the schematic of a three-finger palpation measurement system for data acquisition and wireless data communication. The detailed schematic information is described in the experimental section and demonstrated in Figure S7. Figure 5b shows three-finger palpation results in Chi, Cun, Guan locations. The Guan location shows the largest $\Delta R/R_0$, followed by Cun and then Chi positions.
Figure 5c shows the single-region measurement of pulse pattern under light pressure, medium pressure, and heavy pressure on the Guan location (Video S1, Supporting Information). These results show that the proposed fingertip pressure sensor can be easily utilized by TEAM doctors to analyze the patient’s wrist pulse wave. Although the patient is the same, different doctors sense the wrist pulse waves and analyze it them differently. Therefore, the proposed device will help to improve the analysis of the wrist pulse wave and to obtain more reliable data. In contrast to the previously proposed devices, the proposed device gives a chance to sense the patience wrist pulse directly while the doctor wears the device due to the soft properties of the device. This will be beneficial for the TEAM doctors in two ways. First, the trainee doctors will easily learn and understand how to sense and analyzes the wrist pulse waveforms with real time visualization of wrist pulse while they sense the wrist pulse waveforms by palpation. Second, with the reliable data recorded from the device, the doctors will have an opportunity to match the sensation results and real time pulse waveforms to diagnose the patients more accurately.
Figure 6. Application of the fingertip pressure sensor to Human-Machine Interface (a) Relative resistance change response to the applied pressure for remote controlling of an LED array (b)
Output as LED turn on-off and light brightness corresponding to the applied pressure. (c) Image of Flappy Bird game application. Gravity is applied to the bird that push it toward the ground, and the applied pressure lifts the bird upward against the gravity.

**Application 2: Human-Machine Interface**

We demonstrated a remote control of an LED array and Flappy Bird game to verify the possible applications of human-machine interface using the proposed wearable fingertip pressure sensor, as shown in Figure 6. Figure 6a-c shows the applications of fingertip pressure sensor on the LED light brightness. The detailed schematic of wireless communication system of fingertip pressure sensor and LED illumination setup is illustrated in Figure 6a and S8. Figure 6b shows a relative resistance change by gradual increase of applied pressure for remote controlling of LED. Here, it is demonstrated that the brightness of the LEDs increases depending on the applied pressure level. Nowadays, wearable devices are utilized for entertainment purposes and they have superior user
satisfaction rate. To demonstrate the high potential applicability of our wearable fingertip pressure sensor in entertainment systems, we used the fingertip pressure sensor to play Flappy Bird game.

The gravity is applied to the bird and the location of the bird is adjusted with the pressure measured by the fingertip pressure sensor as shown in Figure 6c and S9 (Video S2, Supporting Information).

The pressure sensor is able to detect small pressures applied by the fingertip and move the bird upward according to the applied pressure, which demonstrates a useful application of the proposed wearable sensor to the entertainment system.

CONCLUSION

In the present work, we have introduced a pressure sensitivity controllable soft liquid metal-based pressure sensor assisted by 3D printed microbumps to resolve the problems of low pressure sensitivity and unstable interconnection of the conventional liquid metal based soft pressure sensors reported in the literature. We investigated the controllability of the pressure sensitivity depending on the microbump dimensions and optimized two microbump configurations (E-bump and A-bump) for a wearable pressure sensor application. The E-bumps are useful if the pressure sensitive area of the liquid metal-based pressure sensor needs to have a high-pressure sensitivity.
Conversely, in the interconnection area, which needs to have relatively low-pressure sensitivity and high signal stability against external stimuli, the A-bumps are utilized. Specifically, the E-bump structure increases the average sensitivity of the liquid metal channels by 5.43 times (0.0727 kPa$^{-1}$), and the A-bump structure decreases the average sensitivity by 91.65 times (0.0004 Pa$^{-1}$) in the range of 0-50 kPa.

Making use of the advantages provided by the E-bumps and A-bumps (for the specific purposes), we integrated them to construct a fingertip pressure sensor for two different wearable sensing applications: 1) a wearable three-fingertip pulse palpation device to help TEAM doctors to measure and collect data related to the pulse patterns from the Cun, Guan and Chi positions of a human wrist. 2) a wearable fingertip pressure sensor for human-machine interface. The proposed fingertip pressure sensor will provide many different opportunities with reliable data acquisition for TEAM doctors to analyze wrist pulse waves. On the other hand, the fingertip pressure sensor can be utilized in the wearable gaming platforms with high user-friendliness. The proposed approach to control the pressure sensitivity of the liquid metal-based pressure sensor using different rigid microbump designs will be a very useful and versatile strategy for improving the performance and stability of many liquid metal based wearable devices.
EXPERIMENTAL SECTION

**Materials:** Dragon Skin™ 10 (Smooth-on, USA), Easy Release™ 200 (Smooth-on, USA), Ecoflex00-35 (Smooth-on, USA), Alja-Safe® (Smooth-on, USA), Hydrocal® (Smooth-on, USA), PVA filament (2.75 mm, Ultimaker, USA), PLA filament (2.75 mm, Ultimaker, USA), Galinstan (Santech Materials, China) were all used as purchased.

**Preparation of the 3D-printed mold:** Microchannel molds were designed with 3D CAD program (Fusion 360, Autodesk, USA). The width of the microchannel was designed as 0.7 mm and the gap between the microchannels at the sensing region was 0.7 mm. The thickness of the sensing region was 0.2 mm and that of the electrode was also 0.2 mm (**Figure S2**). The dimensions of the E-bump and A-bump were 0.4 × 1 × 0.4 mm and 1.5 × 3 × 0.4 mm (width, length, thickness), respectively. After the modeling, the 3D CAD file was exported as STL file for 3D printing and loaded in the 3D printing software program (Cura 3.2, Ultimaker, USA). The microchannel molds were 3D-printed using a commercial FDM 3D printer (Ultimaker 3, Ultimaker, USA) having a dual extrusion system. The molds were 3D-printed with customized printing conditions. After the printing, the molds were carefully detached from the printing bed.
Fabrication of the fingertip pressure sensor:

**Sensor Fabrication Process:** Before spin coating, the release agent was coated on the glass wafer for easy release of the elastomer. The pre-polymer mixture of Dragon SkinTM 10 was prepared by mixing its components, A and B, with a ratio of 1:1 and spin-coated (400 rpm, 60s) on the prepared wafer as the bottom layer, followed by degassing in the vacuum chamber and curing at 60°C. Then, the microchannel molds were put on the bottom layer and the additional pre-polymer was spin-coated (250 rpm, 60s) above them as the top layer, followed by degassing. After curing, small holes were generated at the end of the molds for PVA removal. Deionized water at 60°C was used for consecutive water intrusion into the channel by a syringe and then empty microchannel structure was fabricated. Then, fabricated microchannel was filled with Galinstan by vacuum filling method or syringe injection. Afterwards, the holes were sealed with additional elastomer.

The next step is the integration of pressure sensor to fingertip.

**Fingertip Glove Integration Process:** To integrate the pressure sensor to the fingertip glove, hand shaped bulk mold is needed to prepare by molding and casting process. The hand was immersed into the Alja-Safe® which is mixed with water and waited to cure for 10 mins. Once the Alja-
Safe® was set to a firm solid gel, the hand was carefully removed from the mold. Alja-Safe® perfectly captured the hand shape and the mold was ready for the casting process. Hydrocal® was dispensed into containers with mix ratio of 2-parts plaster: 1-part water by volume and mixed. The Hydrocal® was slowly sifted in to the water. The water absorbed the powders for 2 minutes before stirring. Hydrocal® and water was mixed for a minimum of 4 minutes and filled the cavity with the liquid Hydrocal®, followed by curing for an hour at room temperature. The prepared pressure sensor was attached to the finger of the hand mold with a glue stick. After the placement, Dragon Skin™ 10 was poured onto the pressure sensor and cured at 60°C for 10 mins.

**Sensor characterization:** To measure the cyclic response and pressure response of the sensor, a micro-actuator (MA-35, Physik Intrumente, Germany) and a force transducer (SM-500N, Interface, USA) were used under displacement control loading conditions.

**Wireless Traditional East Asian Medicine Wrist Blood Pressure Monitoring, Game Controlling and Remote Controlling System:**

The sensor and the reference resistor were connected in series for a voltage dividing circuit (**Figure S5a**). The regarded application system was divided into two parts: wireless communication
platform and computer. The wireless communication platform consisted of ADS1115 (Texas Instruments, USA), Arduino Nano (Arduino.cc), Li-Po battery (Shenzhen Taiwoo Batteryco., Ltd, China) and HC-06 Bluetooth module (Arduino.cc). The fabricated fingertip pressure sensor was connected to the ADS1115 which provided a 16-bit precision at 860 samples/second over I2C. The amplified signals were recorded by Arduino Nano. The power of the system was supplied by Li-Po battery. The wireless communication of the system was constructed with HC-06 Bluetooth module. The signals were delivered to the computer by the wireless communication platform and received by oscillator program in computer. The fingertip pressure sensors were inserted to the fingers and placed to the Cun, Guan, Chi areas to measure wrist pulse of the 3 different areas simultaneously for TEAM wrist pulse monitoring. The acquired ADC data were plotted and recorded in real time by a serial oscilloscope program. The second application of the fingertip pressure sensor was remote controlling of the LED array. The signals acquired from wireless communication platform was received by Arduino Due that remotely controlled the LED array. The third application of the fingertip pressure sensor was game controlling. The game programming of game controlling system was done in ProcessingTM program (processing.org, USA). The game principle is that the bird flies and its longitude is controlled depending on the
applied pressure level, and the bird passes through to the walls. Also, gravity is applied in the
game. The pressure sensor signal acquired from wireless communication platform was received
by computer and used for the game control.

Pressure sensor. $k_t$: thickness ratio of microbump to top elastomer layer ($t_b/z$). $k_w$: width ratio of microbump to liquid metal channel ($w_b/w_0$). (b,c) Effect of $k_w$ and $k_t$ on $\chi$. When $k_t$ and $k_w$ approach 1, $\chi$ also approaches to 1, which is theoretically a complete transmission of pressure from the surface to microchannel. (d) FEM simulation of the integration of microbump. (e) $\chi$ vs Arc length when $k_w=1$. When $k_t=0$, there is a parabolic distribution of $\chi$ with respect to the arc length (black dotted curve). Here, the black solid line represents the average $\chi$ for the
parabolically distributed $\chi$ values. However, when the microbump is integrated, there is a constant $\chi$ with increased value across the arc length. (f) $\chi$ vs Arc length when $k_t=0.7$. Only the surface where microbump exist has a constant value and the other part shows a parabolic curve of $\chi$. (g, h) Effect of $k_w$ and $k_t$ on $E_{\text{eff}}$. Black solid curve represents change of $E_{\text{eff}}$ by varying $k_t$ while $k_w$ is fixed at 0.5. Blue dotted curve represents the change of $E_{\text{eff}}$ by varying $k_w$ while $k_t$ is fixed at 1. As $k_t$ and $k_w$ approach 1, $E_{\text{eff}}$ decreases by more than 10%.
Figure 3. Design of microbump with respect to the value of $k_t$ and $k_w$. (a) Single microchannel sensor test for the evaluation of the effect of microbump (Scale bar = 10mm). (b) Effect of $k_t$. When $k_t$ approaches 1, the sensitivity significantly increases. (c) Effect of $k_w$. When $k_w$ is below 1, there is an increase of the sensitivity by increasing $k_w$. When $k_w$ is larger than 1, A-bump prevents the deformation of microchannel, decreasing the sensitivity. (d) 10,000 cyclic loading with the repeating compressive pressure of 0-15 kPa. (e) Effect of length of microbump on bending. L=1 mm, 4mm, and 1/1 mm cases are experimentally observed. Negligible signal change was observed when L is 1 mm and 1/1 mm. (i.e. two 1 mm long microbumps are integrated with a gap of 1 mm).
sure sensor that is based on a 3D-printed rigid microbump integrated liquid metal-based pressure sensor (b) Relative resistance change of the sensing area with/without embedded microbump under applied pressure. (c) Relative resistance change of the interconnection area with/without anchored microbump under pressure. (d) Dynamic response of the sensor to varying pressure application.
